

1. Given Conventions.

(side view sliced in the middle)

- μ is for physics of limb-darkening
(at what depth photons are coming out)
- r is needed for geometry
(how far from star centre is light coming)

d = distance between centres

$$z = d / r_*$$

$$p = r_p / r_*$$

flux = energy per unit time per detector area

the most flux observer receives is during out of transit. When transit occurs, flux drops. We record the normalised flux for light curves, F .
